Abstract The right temporoparietal junction (rTPJ) is frequently associated with different capacities that to shift attention to unexpected stimuli (reorienting of attention) and to understand others' (false) mental state [theory of mind (ToM), typically represented by false belief tasks]. Competing hypotheses either suggest the rTPJ representing a unitary region involved in separate cognitive functions or consisting of subregions subserving distinct processes. We conducted activation likelihood estimation (ALE) meta-analyses to test these hypotheses. A conjunction analysis across ALE meta-analyses delineating regions consistently recruited by reorienting of attention *and* false belief studies revealed the anterior rTPJ, suggesting an overarching role of this specific region. Moreover, the anatomical difference analysis unravelled the posterior rTPJ as higher converging in false belief compared with reorienting of attention tasks. This supports the concept of an exclusive role of the

posterior rTPJ in the social domain. These results were complemented by meta-analytic connectivity mapping (MACM) and resting-state functional connectivity (RSFC) analysis to investigate whole-brain connectivity patterns in task-constrained and task-free brain states. This allowed for detailing the functional separation of the anterior and posterior rTPJ. The combination of MACM and RSFC mapping showed that the posterior rTPJ has connectivity patterns with typical ToM regions, whereas the anterior part of rTPJ co-activates with the attentional network. Taken together, our data suggest that rTPJ contains two functionally fractionated subregions: while posterior rTPJ seems exclusively involved in the social domain, anterior rTPJ is involved in both, attention and ToM, conceivably indicating an attentional shifting role of this region.

Introduction

The human temporoparietal junction (TPJ) is a supramodal association area located at the intersection of the posterior end of the superior temporal sulcus, the inferior parietal lobule, and the lateral occipital cortex. It integrates input from the lateral and posterior thalamus, as well as visual, auditory, somesthetic, and limbic areas (Bzdok et al. 2013a; Mars et al. 2012b; Nieuwenhuys et al. 2007).

Functionally, in particular the right TPJ (rTPJ) has been associated with—at least at first sight—quite distinct cognitive processes (Corbetta et al. 2008; Decety and Lamm 2007; Mars et al. 2012b; Young et al. 2010). On the one hand, its influential role in attentional tasks, e.g. the detection of deviant stimuli in oddball paradigms (Bledowski et al. 2004; Vossel et al. 2008), has been demonstrated in many functional magnetic resonance imaging (fMRI) studies (Arrington et al. 2000; Corbetta et al. 2000; Jakobs et al. 2009; Macaluso et al. 2002). On the other hand, rTPJ has been frequently implicated in social cognition tasks, such as perspective taking or empathy (Hooker et al. 2010; Lombardo et al. 2009). Above all, it has been found to be involved in reorienting of attention and theory of mind (ToM; Corbetta et al. 2008; Decety and Lamm 2007; Mars et al. 2012b; Young et al. 2010).

Reorienting of attention is defined as the capacity to alter the focus of attention to unexpected, external stimuli while actually expecting another task/situation (rTPJ as a ‘circuit breaker’; see Corbetta et al. 2008 for a review). The ability to do so is essential for survival, as human beings have to be capable to respond quickly to unexpected events in their surroundings. Reorienting of attention has been frequently investigated using the Posner task. Cues are shown to indicate whether a target appears on the right or the left side of a screen (Fig. 1; Giessing et al. 2004; Mayer

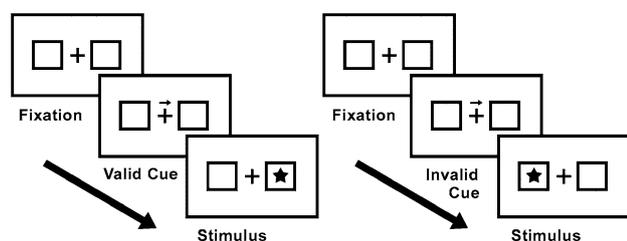

Fig. 1 Example of a typical Posner reorienting of attention task in which cues are shown to indicate whether a target (*asterisk*) appears on the *right* or the *left* side of the screen (here indicated by *two rectangles*). A valid cue (*left*) is presented in 80 % of the trials, whereas an invalid cue (*right*) is shown in 20 % of the trials. Valid cues correctly predict the position of the target. Invalid trials include miscued targets where an *asterisk* suddenly appears on the opposite, uncued position. The contrast invalid versus valid trials finally reveals the reorienting effect and accordingly displays the costs it takes to externally shift attention

et al. 2006; Posner et al. 1980). In the original version of the Posner task, the actual target is presented on the cued side (valid trials) on 80 % of the trials, and on the remaining 20 %, the target appears on the opposite position (invalid trials). The (fMRI) contrast invalid versus valid trials depicts the reorienting effect, i.e. it displays the costs to shift attention from a cued location to an uncued one and unravels the corresponding neural mechanisms.

ToM, in contrast, is an indispensable function in successful human social relationships as it enables people to understand and predict others’ mental states (Saxe et al. 2004). ToM capacities are typically tested with the aid of false belief paradigms, such as the Sally–Ann task (Fig. 2; Wellman et al. 2001; Wimmer and Perner 1983). It belongs to the change-of-location tasks in which first Sally puts a marble into a basket. While Sally is away, Ann quickly puts the marble into another box. Then, the subjects are asked at which location Sally will search for the marble. Hence, the participants have to perform a shift in mental states and breach with their former expectation (true location) to understand Sally’s false belief of the location of the marble. This involves inhibiting their intuitive response of naming the true location.

Although at first glance, reorienting of attention and ToM seem to be two rather independent cognitive processes, there is also evidence for some overlap across these different domains from a developmental as well as clinical perspective. During typical development, the abilities to shift attention and to engage in joint attention with others seem to be important prerequisites for ToM development during infancy (Mundy and Newell 2007). With respect to neuropsychiatric disorders, subjects with attention deficit hyperactivity disorder (ADHD) and autism spectrum

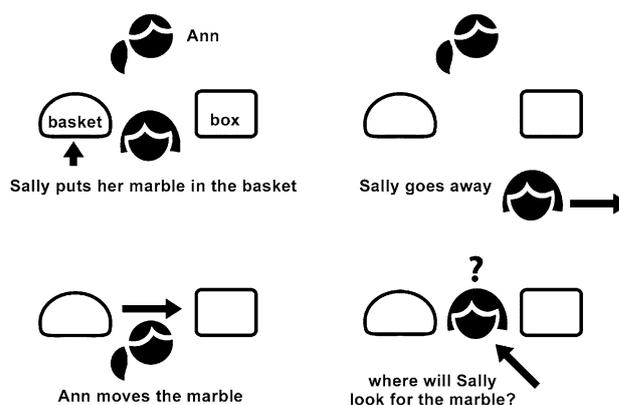

Fig. 2 Example of a Sally–Ann task. First Sally puts a marble into a basket. While Sally is away, Ann quickly puts the marble into another box. Hereafter, subjects are asked at which location Sally will search for the marble. Hence, the participants have to perform a shift in mental states to understand Sally’s false belief of the location of the marble

disorder (ASD) often show deficits in attentional functions and social cognition (Elsabbagh et al. 2013; Uekermann et al. 2010). Even though the previous literature primarily focused on attentional deficits in ADHD and social disturbances in ASD, more recent literature pointed out social *and* attentional deficits in both disorders. This suggests an interdependence of the two cognitive domains and may indicate shared neural mechanisms. However, to date, rTPJ's involvement in attention and social cognition remains to be elucidated. This debate is further complicated by the absence of commonly accepted micro- and macroanatomical landmarks to define the exact location of this functional region, as well as by uncertainties about homologous areas in nonhuman primates (Bzdok et al. 2013a; Mars et al. 2012b, 2013).

Generally, two competing views on the role of the rTPJ have been put forward: (1) the *overarching view* assumes that rTPJ indeed represents a unitary region that is involved in separate functions (cf. Cabeza et al. 2012). It has been hypothesized that reorienting of attention and false belief activate the rTPJ since both functions rely on the shared phenomenon of breach of expectation (Corbetta et al. 2008) or require a 'where-to' function (Van Overwalle 2009). This is in line with the *attention hypothesis*, which poses that shifting between mental states as required in false belief tasks (or more general ToM tasks) can be interpreted in terms of attentional shifting (reorienting of attention; cf. Young et al. 2010). By contrast, (2) the *fractionation view* assumes that the rTPJ consists of a number of—yet to be defined—separate subregions involved in distinct cognitive processes (cf. also Cabeza et al. 2012). In line with this view, it has been demonstrated that the rTPJ can be subdivided into at least two subregions (anterior and posterior rTPJ) on the basis of its structural and functional connectivity (Bzdok et al. 2013a; Mars et al. 2012b).

To date, only few experimental studies directly examined the relative contribution of the rTPJ in attention and social cognition in order to test whether they reflect the same or different functions in relation to the attention hypothesis. So far, these fMRI studies provided conflicting results. While Mitchell (2008)—in line with a meta-analysis by Decety and Lamm (2007)—reported spatial overlap between rTPJ activations during attentional selection (reorienting of attention) and attribution of beliefs (ToM), Scholz et al. (2009) obtained contrary findings. Here clear-cut inferior–superior segregation was identified in the rTPJ by a bootstrap analysis.

Thus, to date, the debate on the role of rTPJ in reorienting of attention and false belief remains controversial. The inclusion of findings based upon relatively small sample sizes as well as variations in naming of certain brain regions and, consequently, inexact localization of neural activations may all have contributed to the

heterogeneity of previous findings (Bzdok et al. 2013a). One way to overcome these limitations is to identify convergent regions of activation over multiple studies by random effect meta-analysis, using the activation likelihood estimation (ALE) method (Eickhoff et al. 2009; Turkeltaub et al. 2002). This approach allows estimating the probability at each location in the brain that a reorienting of attention or false belief study would report a focus of activity, given the underlying set of analysed neuroimaging studies. It thus identifies brain regions with statistically significant convergence across the input studies.

Recent ALE meta-analyses have already reviewed the role of the rTPJ from different perspectives (Bzdok et al. 2012; Decety and Lamm 2007; Geng and Vossel 2013; Kubit and Jack 2013). However, previous meta-analyses did not directly test the overarching versus fractionation view in association with the attention hypothesis (primarily focussing on the concepts of reorienting of attention and false belief). They included studies on agency and empathy (besides ToM) as well. In addition, in the study by Decety and Lamm (2007), the selection of studies was a priori restricted to studies demonstrating TPJ activity (primarily defined by the authors as posterior superior temporal sulcus and inferior parietal lobule/angular gyrus). This led to a biased statistical ALE analysis.

Contrary to those previous studies, we here focus on two homogeneous concepts, namely, reorienting of attention and false belief. In these experiments, the requirements for a breach of expectation (Corbetta et al. 2008) and mental state shifting (Van Overwalle 2009) in union with the attention hypothesis are maximal. As a consequence, only fMRI and PET studies that used reorienting of attention tasks—similar to the classic Posner version—or false belief experiments—resembling the classic Sally–Ann tasks—were included. If the overarching hypothesis was true, an overlap of the two cognitive tasks in the rTPJ due to their common role in state shifting would be expected. Based on this concept, it is hypothesized that both—reorienting of attention and false belief—rely on some fundamental form of switching attention either from previously expected stimuli (reorienting of attention) or mental states (false belief). In contrast, according to the fractionation hypothesis, distinct neural mechanism of false belief and reorienting of attention in the rTPJ would be predicted. To further evaluate potentially separate functional modules within the rTPJ based on the results of our ALE meta-analysis, we performed task-restricted meta-analytic connectivity mapping (MACM) and task-free resting-state functional connectivity (RSFC) analyses on the ensuing significant findings within the rTPJ.

Methods

Selection of studies

Neuroimaging experiments to be included in this current meta-analysis were obtained through PubMed (<http://www.pubmed.org>). Further studies were identified by review articles and reference tracing of retrieved studies. The following key words were used in order to identify relevant studies: For *reorienting of attention studies*: functional fMRI OR positron emission tomography (PET) AND reorienting OR orienting OR valid OR invalid OR validity OR congruent OR incongruent OR congruency OR Posner OR attention OR attention network test (ANT). For *false belief studies*: fMRI OR PET AND ToM OR false belief OR true belief OR perspective taking OR perspective shifting. Note, we did not use (r)TPJ as a key word in the literature search.

Additionally, only fMRI and PET studies with random effects and whole-brain group analyses were enclosed, while single-subject findings and region-of-interest analyses were excluded. Studies were included only if they reported results either in Talairach (TAL) standard reference space or Montreal Neurological Institute (MNI) coordinate space. The coordinate space was matched by transforming TAL coordinates into MNI coordinates by means of a linear transformation (Lancaster et al. 2007). All analyses were consequently performed in MNI space. Experiments addressing any pharmacological manipulation, brain lesions, mental/neurological disorders, connectivity analyses, transcranial magnetic stimulation, genetic effects, or data on children and elderly were excluded.

Several fMRI/PET studies allowed the extraction of multiple experiments. For instance, the study by Döhnell et al. (2012) comprised a false belief task versus distinct control conditions leading to various suitable experiments to be enclosed (see Tables 1, 2 for an overview of false belief and reorienting of attention experiments). Therefore, based on these studies, data from the same set of subjects entered the final ALE analysis more than once. Overall, the average number of contrasts enclosed in the ALE analysis was approximately 1.15 (54 contrasts from 47 studies). A significant influence of a single-subject population is therefore extremely unlikely. The inclusion of a high number of contrasts (total of 54) further ensured the robustness of the current ALE meta-analysis results.

The attentional reorienting category enclosed in the statistical meta-analysis is best represented by the Posner task contrast ‘invalid–valid’ including the essential invalidity effect. Attentional studies using the attention network task (e.g. Fan et al. 2005), oddball tasks (Bledowski et al. 2004), or studies testing the detection/translation of sensory information (Geng and Mangun 2011) were explicitly

excluded as these types of tasks/studies do not involve the targeted ‘reorienting of attention’ effect. The included experiments comprised auditory, visual, haptic, or cross-sensory studies as well as diverse versions of cues (e.g. arrows; see Table 1 for an overview of all reorienting of attention studies). In studies using variable stimulus onset asynchronies (SOAs), only those with short SOAs were enclosed to minimize the danger of an accidental inclusion of an inhibition of return effect. Moreover, to ensure homogeneity, only contrasts with a minimum ratio of 1:3 (invalid vs. valid) were included, as only these contrasts lead to an invalidity (top-down) effect (Alvarez and Freides 2004). Coordinates were also extracted for three studies, which were based on a combination of a 50/50 contrast (including 50 % invalid and 50 % valid trials) and the preferable ratio. This was done as these only led to differences in intensity of the activations, but not in the locations themselves (for the ALE analyses only the location matters).

In the case of false belief studies, solely those experiments were included which contrasted a false belief condition to (variable) control conditions. The stories and cartoons highly resembled typical Sally–Ann tasks, which best encompassed the requested ‘breach of expectation’ (Corbetta et al. 2008) and ‘mental shifting’ (Van Overwalle 2009) effects. The control conditions comprised, for example, true belief attribution, false photograph stories, or unlinked sentences. In general, the inclusion of multiple false belief studies ensured that our results are not an artefact of a specific contrast, but pinpoint the concept of false belief reflected in various task combinations used in previous studies (cf. also Dodell-Feder et al. 2011). Table 2 shows an overview of all false belief and control studies.

Data analyses

A total of 25 experiments for reorienting of attention and 29 studies for false belief met all inclusion criteria for the meta-analysis. Overall, 798 subjects [note that for the reorienting of attention and false belief experiments extracted from Mitchell (2008), the very same set of subjects was measured] and 449 activation foci (3D peak coordinates) were included in the final analyses.

All analyses were accomplished using the revised ALE algorithm for coordinate-based meta-analysis neuroimaging results (Eickhoff et al. 2009, 2012; Laird et al. 2009a, b; Turkeltaub et al. 2002, 2012). The main goal of ALE is the identification of cerebral regions revealing convergences of 3D peak coordinates across contrasts, which have to be higher than expected under a random spatial association in order to be considered significant. Importantly, the peak coordinates reported in the respective papers were modelled not as single points, but as centres for 3D

Gaussian probability distributions, thereby acquiring spatial uncertainty correlated with each point. The width of the 3D Gaussian probability distribution was calculated based on the between-subject and between-template variance. This was done by an algorithm weighting the between-subject variance by the number of participants per experiment, building on the assumption that larger sample sizes yield more reliable results. Therefore, these have to be modelled by smaller Gaussian distributions (Eickhoff et al. 2009).

Probability values of all foci in a particular experiment were calculated and combined for each voxel, resulting in one modelled activation (MA) map per experiment (Turkeltaub et al. 2012). The union of these MA maps across experiments was then computed, resulting in voxel-wise ALE scores reflecting the convergence of results at each location. In the next step, ALE scores were compared against a null distribution reflecting the random versus true convergence of regions across the brain. The null

distribution was acquired by an analytical solution of a randomization procedure (Eickhoff et al. 2012) consisting of randomly sampling a voxel from each of the MA maps and subsequently taking the union of these values (analogously as in the true analysis).

The p value of a “true” ALE is then given by the proportion of equal or higher values obtained under the null distribution. These nonparametric p values for each meta-analysis were then thresholded at a cluster-level corrected threshold of $p < 0.05$ (cluster-forming threshold at voxel level $p < 0.001$) and transformed into Z scores for display. A Monte Carlo simulation was performed of the excursion set above a cluster-forming threshold founding on an analysis of randomly distributed foci under otherwise identical context. This simulation was implemented to gather an extent threshold to control for the cluster-level FWE rate. A final null distribution of above threshold cluster sizes was derived from 10,000 simulations of these random analyses. This

fMRI functional magnetic resonance imaging, TAL Talairach standard reference space, MNI Montreal Neurological Institute coordinate space

distribution was then used to identify the cluster size, which was only exceeded in 5 % of all random realizations (reflecting the critical threshold for cluster-level FWE correction). Finally, a grey matter mask was applied to exclude coordinates located in deep white matter.

Individual ALE analyses reorienting of attention and false belief tasks

For the reorienting of attention contrast, 25 experiments (358 subjects and 203 foci) were chosen as a basis for the identification of regions showing convergence across reorienting of attention studies higher than expected under a random spatial association. For the false belief contrast, 29 experiments (460 subjects and 246 foci) were chosen to determine converging activation clusters. Both analyses

were cluster-level family-wise error (FWE) corrected at $p < 0.05$.

Conjunction ALE analysis reorienting of attention and false belief tasks

Both individual meta-analyses were then combined into a conjunction analysis. The major aim of this analysis was to identify those voxels showing a significant effect in both individual analyses (reorienting of attention and false belief). The conservative minimum statistic (Nichols et al. 2005) was used to perform the conjunction analysis, which is identical to the voxel-wise minimum between two cluster-level FWE corrected results (Caspers et al. 2010). Therefore, only areas that were significant in the individual analyses were included. An additional extent threshold of $k > 15$ voxels was applied to exclude those regions

showing incidental overlap between the ALE maps of the separate analyses.

Difference ALE analyses reorienting of attention versus false belief tasks

Difference analyses allowed identifying those areas of activation which converged significantly more for either reorienting of attention or false belief studies. This was analysed by performing individual ALE analyses for both studies and computing voxel-wise differences between the ensuing ALE maps (Eickhoff et al. 2012). In a subsequent step, all experiments were pooled and randomly divided into two groups. These artificially created groups were identical in size as the two original data sets. Consequently, ALE scores for the randomly assembled groups were calculated, and the voxel-wise difference was documented. This process was repeated 10,000 times generating an expected distribution of ALE score differences based on an exchangeability assumption. The actual “true” difference score was then contrasted against this null distribution. The final probability values were thresholded at $p > 0.95$ (95 % chance for true difference) and masked by the main effects of reorienting of attention and false belief.

Comparison of conjunction and difference ALE analyses

A conjunction analysis aims at identifying overlapping convergences of brain activity across both reorienting of attention and false belief experiments, whereas the main goal of the difference analyses is the identification of areas more strongly associated with one or the other task, i.e. either false belief or reorienting of attention. Therefore, contrasting reorienting of attention with false belief tasks reveals locations where a significantly stronger convergence exists among the former relative to the latter. Nevertheless, this does not preclude a significant convergence of the latter. Even in areas where significantly stronger convergence of activation is reported in reorienting of attention, the convergence reported for false belief tasks might be significant as well. Consequently, both the contrast as well as the conjunction would be significant at the very same location. Therefore, contrast and conjunction effects are not mutually exclusive, but strictly complementary (cf. Rottschy et al. 2012).

Follow-up analyses: MACM and RSFC: anterior and posterior rTPJ

In order to identify whole-brain connectivity patterns for the anterior ($x = 54$, $y = -44$, $z = 18$; $Z = 4.61$, 111 voxels) and posterior rTPJ ($x = 54$, $y = -52$, $z = 26$; $Z = 6.5$, 519 voxels; as identified in the conjunction and

difference analyses, respectively, cf. results) and therefore disentangle their functional modules, MACM and RSFC were assessed (Jakobs et al. 2012; Rottschy et al. 2013). The comprehensive assessment of functional connectivity patterns of certain seed regions was given by performing a meta-analysis unravelling significant co-activation in all experiments activating the respective seed area (MACM), as well as the identification of all voxels in the human brain whose time series in a task-free/resting-state depict significant correlation with the reference time course extracted from the coherent seed. The goal of these follow-up analyses was to test the distinctness of the anterior and posterior rTPJ by different whole-brain connectivity patterns. Task-based MACM determined those regions across the entire brain that significantly co-activated with a specific seed region across a large number of functional neuroimaging experiments. For this purpose, an ALE meta-analysis was performed across all BrainMap experiments (Fox and Lancaster 2002; Laird et al. 2011, 2013; <http://www.brainmap.org>) comprising at least one 3D peak of activation within the clusters. Only fMRI and PET studies were included based on ‘normal mapping’ neuroimaging studies (no interventions and no group comparisons) in healthy subjects and reporting coordinates in either MNI or TAL space. The final implementation of the ALE analysis was identical to the one described in “Data analyses” section. Overall, this approach allowed determining how likely any other voxel throughout the brain was co-activated with the selected seed voxels (cFWE corrected; $p < 0.05$) in contrast to the respective seed region.

Task-free RSFC analysis was performed on the anterior and posterior rTPJ clusters, by which whole-brain connectivity profiles related to the selected clusters were determined by resting-state correlations. Hereby, it was possible to quantify the connectivity strength of the selected clusters with any other voxel in contrast to the second seed region. This was achieved through the calculation of correlations between spontaneous fluctuations throughout the human brain while mind wandering. The RSFC analysis was performed using the Nathan Kline Institute “Rockland” sample, which is accessible online and belongs to the International Neuroimaging Data-sharing Initiative (http://fcon_1000.projects.nitrc.org/indi/pro/nki.html). Overall, 132 healthy volunteers (78 male, 54 female) between 18 and 85 years (mean age: 42.3 ± 18.08 years) for whom 260 RSFC echo-planar imaging (EPI) volumes were collected during rest using blood-oxygen-level-dependent (BOLD) contrast [Siemens TrioTrim 3T scanner; gradient-echo EPI pulse sequence, repetition time (TR) = 2.5 s, echo time (TE) = 30 ms, flip angle = 80° , in-plane resolution = 3.0×3.0 mm, 38 axial slices (3.0 mm thickness) covering the entire brain].

After standard preprocessing steps using SPM8 (Wellcome Trust Centre for Neuroimaging, London, <http://www.fil.ion.ucl.ac.uk/spm/software/spm8/>; see Bzdok et al. 2013a for details), the final time-series data were further processed to account for confounds possibly biasing voxel-wise correlations of BOLD signal time series. This was achieved by iteratively discarding variance which could be explained by nuisance variables (Fox et al. 2009; Weissenbacher et al. 2009). Thereby, BOLD signal fluctuations highly correlated with the six head motion parameters acquired by image realignment and the first derivative of the realignment parameters were removed. Furthermore, the mean grey/white matter and cerebrospinal fluid (CSF) signal per time point derived by averaging across voxels associated with the respective tissue class in the SPM 8 segmentation were discarded. Finally, these nuisance variables entered the model as first-order and second-order terms (Jakobs et al. 2012; cf. Satterthwaite et al. 2013 for an evaluation of this framework). Data were band-pass filtered removing frequencies outside the 0.01–0.08 Hz range (cf. Biswal et al. 1995; Fox and Raichle 2007). The time-course correlations (after temporal preprocessing) between every individual seed voxel with any other voxel throughout the brain were calculated. The final correlation values were then transformed into Fisher's Z scores and documented in a connectivity matrix. Here, we contrasted whole-brain connectivity estimates computed for the anterior rTPJ and posterior rTPJ (and vice versa), which allowed to determine those regions in the whole brain showing significantly higher connectivities with the one or the other seed region.

Finally, to delineate those areas showing both task-dependent and task-independent functional connectivity with the anterior and posterior rTPJ in contrast to each other, a conjunction analysis on MACM and RSFC results was carried out (Jakobs et al. 2012; Rottschy et al. 2013) by the strict minimum statistic (cf. above). Hence, those regions co-activated with the seed clusters were outlined by the computation of the intersection of the connectivity maps derived by MACM and RSFC. Hereby, networks of cerebral regions correlated with the anterior versus posterior rTPJ were identified that are robustly connected in both task-related (MACM) but also task-free (RSFC) brain states. Furthermore, a conjunction analysis across anterior and posterior rTPJ (across MACM and RSFC) was performed identifying those regions showing a significant effect in both individual connectivity analyses (see “[Conjunction ALE analysis reorienting of attention and false belief tasks](#)” section for a description of the conjunction procedure).

Labelling

Clusters were anatomically labelled with respect to their most probable macroanatomical and cytoarchitectonic

location using the Anatomy Toolbox (Eickhoff et al. 2005, 2007), an SPM plugin (Wellcome Trust Centre for Neuroimaging, London, <http://www.fil.ion.ucl.ac.uk/spm/software/spm8/>). Foci of activations were attributed to their most likely histological cerebral region at their corresponding location by recourse to a maximum probability (MA) Map from the Jülich brain atlas (Amunts et al. 1999; Caspers et al. 2006; Geyer 2004; Gitelman et al. 1999). Note, however, that the rTPJ has not yet been mapped cytoarchitectonally, making it difficult to apply neuroanatomically well-defined labels (Bzdok et al. 2013a; Mars et al. 2012b; Mitchell 2008). Final peak maxima are presented in MNI space.

Results

Individual ALE analyses reorienting of attention and false belief tasks

The ALE meta-analysis of 25 reorienting of attention experiments unravelled consistent activations (ordered from biggest to smallest cluster) in the rTPJ, the right inferior frontal junction (cf. Brass et al. 2005 for a labelling of the inferior frontal junction), bilateral inferior parietal lobule, bilateral precuneus, and the right insula lobe.

The ALE meta-analysis of 29 false belief experiments revealed the rTPJ, ITPJ, bilateral superior medial gyrus, left posterior cingulate cortex, and bilateral middle temporal gyrus as converging clusters. Table 3 presents the results for the peak maxima identified by the individual ALE analyses on reorienting of attention and false belief tasks.

Conjunction ALE analysis reorienting of attention and false belief tasks

The conjunction analysis showed the anterior rTPJ ($x = 54$, $y = -44$, $z = 18$; $Z = 4.61$, 111 voxels) as the only brain region consistently activated across reorienting of attention and false belief tasks. Figure 3 presents the result of the conjunction analysis. Note that we did not restrict a priori our ALE analyses to TPJ, but entered all maxima across the whole brain.

Difference ALE analyses reorienting of attention versus false belief tasks

Reorienting of attention in contrast to false belief tasks revealed stronger convergence for reorienting of attention in the bilateral inferior parietal lobule and right inferior frontal junction. For false belief tasks in contrast to reorienting of attention, the ITPJ, bilateral superior medial gyrus, left precuneus, posterior rTPJ, and bilateral middle

temporal gyrus were identified. Table 4 and Fig. 4 show the results of the difference analyses.

MACM and RSFC analyses: anterior and posterior rTPJ

Combined MACM and RSFC analyses on the anterior and posterior rTPJ unravelled connectivity patterns for the two regions (see Supplementary Material for individual results of MACM and RSFC difference and conjunction analyses). The *anterior* rTPJ in contrast to the posterior rTPJ co-activated more significantly (ordered in cluster size) with the anterior ITPJ, right inferior frontal gyrus, bilateral middle cingulate cortex, left insula lobe, right precuneus, and right inferior parietal lobule (Table 5; Fig. 5). On the contrary, the *posterior* rTPJ compared with the anterior rTPJ showed connectivity to bilateral precuneus, posterior ITPJ, and right middle temporal gyrus (Table 5; Fig. 5). The identification of converging connectivity between the anterior and posterior rTPJ did not reveal common regions besides the rTPJ itself (including the anterior and posterior subregions; $x = 54$, $y = -48$, $z = 22$; $Z = 8.41$, 1044 voxels).

Discussion

In the following discussion, we will examine present theories on the overlap of reorienting of attention and false belief in the anterior rTPJ and the specific involvement of

the posterior rTPJ in false belief in contrast to reorienting of attention. Additionally, connectivity patterns of the anterior and posterior rTPJ as identified by task-restricted MACM and task-free RSFC analyses will be discussed. These findings gathered by ALE and connectivity analyses will be further interpreted in a more global context considering overarching versus fractionated roles of the rTPJ. Finally, the clinical relevance of this meta-analysis will be highlighted with a special focus on ADHD and ASD.

Shared cerebral region of reorienting of attention and false belief

The conjunction ALE meta-analysis including reorienting of attention and false belief tasks demonstrated an overlap in the anterior rTPJ. This was identified by the voxel-wise conjunction analysis of the two individual ALE meta-analyses. Hereby, *only* the anterior rTPJ significantly converged for both separate ALE analyses across 54 studies. Therefore, the results support the overarching view for this region. Although it has been questioned that reorienting of attention is processed on the same abstract and verbal level as ToM stimuli and hence draws upon the same neural resources (Young et al. 2010), our data suggest the rTPJ is involved in both attention and social interaction. This is at odds with the results of Young et al. (2010) who did not identify an interaction in the rTPJ in a combined reorienting of attention-ToM task. Presumably, because their inclusion of ‘higher-level’ attention stimuli (unexpected/expected endings in verbal stories reflecting reorienting of attention) did not activate the rTPJ as ‘low-level’ reorienting of attention stimuli (as the classic Posner task) would have done. These common mechanism of ‘low-level’ reorienting of attention and false belief might be explained by Corbetta’s breach of expectation (attention shifting), or alternatively Overwalle’s concept of ‘where-to shifting’ (Corbetta et al. 2008; Van Overwalle 2009). Both focus on the capacity to shift attention between states. For reorienting of attention, an attentional shifting capacity is necessary after an invalid cue. For false belief, the very same capacity is needed during mental state shifting to further understand a false belief. Our ALE meta-analysis data can thus be interpreted in the light of the attention hypothesis indicating that false belief is not feasible without successful attentional processes.

Alternatively, one might interpret these findings in the following way: false belief capabilities are needed for successful attention shifting (cf. Mitchell 2008). A reorienting of attention task would then be based on a participant’s trial-by-trial formation of a new belief about the upcoming target. The cost of an invalid cue would therefore represent the shifting or breach of that former (false) belief. A dispute against this link is that other attentional

tasks do activate the rTPJ as well, such as attentional capture tasks using distractors in the same colour as the targets (Serences et al. 2005). In these tasks, one might quite certainly exclude an involvement of a (false) belief formation. Another argument against this interpretation is that lesions in (or near) the rTPJ commonly lead to attentional deficits but not social problems. This is consistent with the assumption of a more general role of attention in the right parietal lobe (Mesulam 1981). Taken together, it seems that the attention hypothesis, where attentional shifting is fundamental for false belief formation, best describes the overlap of reorienting of attention and false belief in anterior rTPJ.

Beyond interpreting these findings in the light of attentional shifting, one might also reconsider the role of the anterior rTPJ in the context of a more domain-global process, such as neural prediction coding (Bzdok et al. 2013a; Koster-Hale and Saxe 2013). Basically, predictive coding can be seen as a ‘neural’ attempt to decrease computational load. This can be achieved by reducing neural responses to predictable input and increasing neural activity to unexpected input (Jakobs et al. 2009). Therefore, incoming information is compared against (learned) expectations rather than being analysed as a new, unknown stimulus. The anterior rTPJ might thus be involved in the working memory formation of predictions about the location of targets (reorienting of attention) and about person’s beliefs (ToM; cf. Koster-Hale and Saxe 2013). Heightened activity in the rTPJ might in consequence be related to the unexpectedness of the input, such as an invalid cue or a question about someone’s false belief. This recognition of an unexpected pattern might further lead to an increase in attention towards these unpredicted stimuli and thus trigger attentional shifting. Therefore, it could be possible that the concept of predictive coding is fundamental to attentional shifting. This renders these two hypotheses not mutually exclusive, but rather complementary.

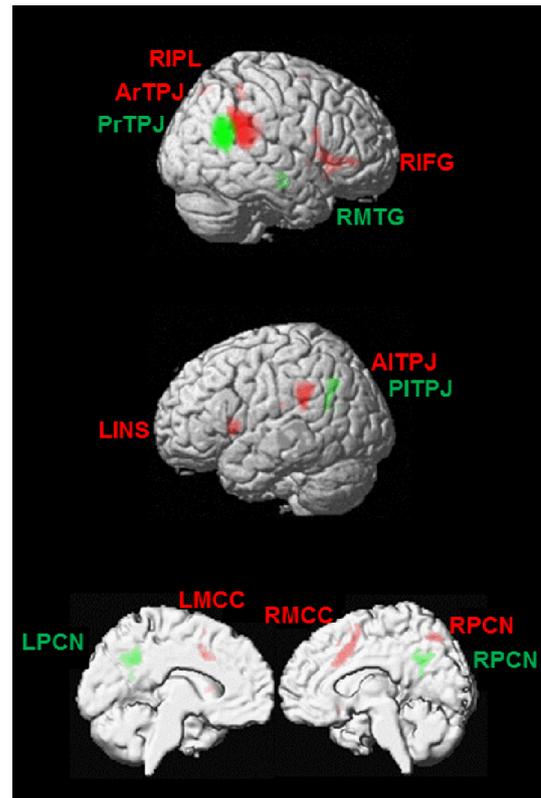

Fig. 5 Distinct connectivity patterns for anterior (red) and posterior (green) rTPJ based on a combination of task-related meta-analytic connectivity mapping analysis and task-free resting-state functional connectivity analysis. The further identification of the posterior rTPJ significantly converging for false belief in contrast to reorienting of attention (in the difference analysis) led to various speculations about the actual distinctness of these subregions: (1) the anterior and posterior rTPJ could indeed represent two functionally distinct subregions of the rTPJ or (2) they reflect transition zones between attentional and social processes. Unfortunately, to date, neuroimaging research lacks an agreement regarding which amount of spatial separation between two clusters justifies the conclusion that these reflect distinct neural activations (Decety and Lamm 2007). In fact, the two peak activation convergences in the anterior (conjunction analysis) and posterior rTPJ (difference analysis) were 16.64 mm apart from each other. This basically already hints towards a relatively clear separation. To thus further unravel these divergent findings (conjunction vs difference analyses) and identify

the distinctness/transition between these areas, we additionally performed post hoc MACM and RSFC. This allowed testing for separate functional connectivity patterns of the two regions in contrast to each other. Moreover, by the intersection of regionally specific architecture and connectivity patterns, a more precise attribution to a certain functional specialization was feasible (Eickhoff and Grefkes 2011). Regions identified in the conjunction analysis over MACM and RSFC co-activations can be regarded as robustly connected with the respective seed regions because of the incorporation in similar networks and the (potential) engagement by the same cognitive functions. Connectivity pattern results gained by task-restricted MACM and task-free RSFC finally indicated distinct connectivity patterns. This supports the assumption that these two foci indeed reflect activations of separate neural networks and do not represent transition zones. The anterior rTPJ seed region in contrast to the posterior rTPJ seed area featured co-activations to a ventral attention network (Corbetta and Shulman 2002). Thus, MACM and RSFC analyses identified the right inferior frontal gyrus, middle cingulate cortex, left insula lobe, right precuneus, and right inferior parietal lobule to co-activate significantly with the anterior rTPJ compared with the posterior rTPJ. Similar connectivity profiles were found in parcellation studies performed by Bzdok et al. (2013a) or Mars et al. (2012b; see supplementary material for a visualization of peak coordinates assigned to the anterior and posterior rTPJ by Bzdok et al. (2013a), Mars et al. (2012b), and the current meta-analysis). Anterior rTPJ activity seemed to significantly increase in alliance with a midcingulate–motor–insular network and was attributed to attentional functions by network mapping and functional forward/reverse inference analyses (Bzdok et al. 2013a). In particular, pain perception, tactile-attentive tasks, action execution, and motor control had been identified with an anterior rTPJ network by functional profiling. Similarly, Mars et al. (2012b) unravelled the anterior rTPJ to be significantly interacting with ventral prefrontal cortex and anterior insula.

The idea of the ventral attention network conceptualizes the rTPJ as a core region of this mostly right-lateralized frontoparietal network (Corbetta and Shulman 2002). It has also been shown that this ventral network reacts to sudden changes not only in visual stimulation, but also in response to auditory and tactile stimuli (Downar et al. 2000). By the inclusion of multiple modalities in reorienting of attention studies in the current ALE meta-analysis, this cross-modality connection is identified too.

Altogether, it seems that the significant co-activation between the anterior rTPJ and the ventral attention network when compared with the posterior rTPJ represents attentional shifting. Strong connectivities to the ventral attention

network/saliency network regions (Corbetta and Shulman 2002; Sridharan et al. 2008) seem to facilitate the allocation of attention to behaviourally relevant stimuli. Thereby, they interrupt automated, predicted routines needed for both reorienting of attention *and* false belief tasks. On the contrary, the posterior rTPJ compared with the anterior rTPJ showed a significant connectivity pattern with a social cognition network. This implies two separate roles for these subregions identified by task-dependent MACM and task-independent RSFC. Therefore, interpreting the ALE and connectivity results from a more systematic perspective, one might rather clearly advocate for a fractionated role of the rTPJ on the whole. The overlap of reorienting of attention and false belief tasks in the anterior part of the rTPJ does not contradict a fractionated view of the rTPJ as tasks are attributable to a common, unique cognitive function: attentional shifting. The connectivity analyses performed in this study enabled investigating this functional overlap through assessing whether certain neural regions are differentially interacting and thereby adding essential information to standard fMRI activations (Eickhoff and Grefkes 2011). It allowed delineation of brain regions not based on activation in a certain task or their structural properties but on their functional coupling properties across distances with either the anterior or posterior rTPJ. Thereby, it enabled generalization beyond the task set (reorienting of attention and false belief) and tested whether the association is steadily expressed over numerous tasks (MACM) or whether it can be reflected in a task-free state as well. The final results depicting separate connectivity profiles for anterior and posterior parts of the rTPJ thus clearly point to a fractionation in the rTPJ into an anterior and posterior part. It seems that the anterior rTPJ and its connected regions aid attentional shifting, while the posterior rTPJ network enables social interaction capacities. The posterior rTPJ and its connectivities are further discussed below.

Specific neural mechanism of false belief

Difference analysis on false belief versus reorienting of attention revealed the lTPJ, superior medial gyrus, left precuneus, middle temporal gyrus, and the posterior rTPJ as showing significantly higher convergence for the false belief task. This specific neural activity pattern related to false belief in contrast to reorienting of attention has also been repeatedly associated with a more global role of recognizing and processing of others' mental states (Gallagher and Frith 2003; Van Overwalle 2009). It is in consonance with other ToM meta-analyses (Bzdok et al. 2012; Decety and Lamm 2007). In particular, the involvement of bilateral TPJ is repeatedly shown in ToM neuroimaging studies, in contrast to attentional

experiments. In attentional shifting studies primarily the rTPJ has been found, but for ToM the ITPJ seems to be specifically involved in verbal compared with nonverbal ToM tasks (Saxe and Kanwisher 2003). In line with a more influential role of the ITPJ in social interaction compared with attention, lesion studies showed that damage to this region frequently results in a belief-reasoning impairment (Apperly et al. 2004). RTPJ damage, on the contrary, results more often in attentional difficulties (Bultitude et al. 2009).

In the context of our MACM and RSFC analyses delineating the differential connectivity of the anterior and posterior rTPJ, a connectivity network for the posterior rTPJ seed region in contrast to the anterior seed was unravelled. The identified correlations with the precuneus, posterior ITPJ, and right middle temporal gyrus have been repeatedly linked to the social cognition network (Bzdok et al. 2013a, b; Mars et al. 2012b; Schilbach et al. 2012). In a connectivity-based subdivision study, it was shown that posterior rTPJ interacted with posterior cingulate, temporal pole, and anterior medial prefrontal cortex (Mars et al. 2012b). Bzdok et al. (2013a) identified that activity in the posterior rTPJ significantly increased with a parietal network which was further functionally decoded to be associated with explicit (notably episodic) memory retrieval, semantic discrimination, social cognition, and theory of mind tasks. Overall, the identified connectivity profile of the posterior rTPJ appears to resemble results from previous studies, especially considering the activations in the precuneus and middle temporal gyrus.

Basically, it has been suggested that the function of the posterior rTPJ network is particularly related to a more internally oriented network, also relating to the default mode network reflecting stimulus-independent mental processes (Bzdok et al. 2013a; Kubit and Jack 2013; Mars et al. 2012a). In general, this network has been identified not only in ToM tasks, but also in other higher social processes, such as perspective taking (e.g. Ruby and Decety 2004; Vogeley et al. 2004), empathy (e.g. Jackson et al. 2006), or agency (see a review by Sperduti et al. 2011), pointing towards a more (domain-) global role of this region in ToM abilities.

Overall, it thus seems that the posterior rTPJ—as a subregion of the rTPJ—shows stronger convergence for false belief in contrast to reorienting of attention as suggested by our difference analysis. It also is an essential part of the social cognition network linked to multiple aspects of ToM as reflected in our MACM and RSFC findings.

Clinical relevance

Social interaction and attention are commonly affected across different neurodevelopmental disorders, such as in

ADHD and ASD (Alvarez and Freides 2004; Korkmaz 2011; Paynter and Peterson 2010). ADHD is typically characterized by difficulties of inattention or hyperactivity or impulsiveness. ASD is marked by social and communication deficits, stereotyped or repetitive behaviours and interests (American Psychiatric Association 2000). Although diagnostic criteria for the two disorders show little overlap, both disorders frequently co-occur. Attention problems, social-cognitive deficits and emotion regulation problems are frequently observed in both ADHD and ASD (see Rommelse et al. 2011 for a review). In addition to behavioural overlap between ADHD and ASD patients, there is increasing evidence for shared genetic (Simonoff et al. 2008), neurocognitive, and brain dysfunction (Brieber et al. 2007). For example, Uekermann et al. (2010) demonstrated in a meta-analysis that ADHD is associated with social cognition impairments, especially face and prosody perception. In addition, a recent meta-analysis on visual orienting in autism (focussing on Posner-type tasks) demonstrated that subjects with ASD indeed showed a small impairment in reorienting of attention compared with controls (effect size across studies: $d' = 0.44$; Landry and Parker 2013). In line with this, Elsabbagh et al. (2013) unravelled an association between anomalies in disengagement of attention in a high-risk group of children (having a sibling with ASD) and ASD at the age of 3 years. Polderman et al. (2013) demonstrated that the link between attention problems (attentional shifting difficulties) and autistic traits in adults could be explained by a shared genetic factor, as assessed in a population-based twin-sibling design. On the neural level, recent studies also suggest that children and adolescents with ADHD and ASD share some cortical and subcortical abnormal brain mechanisms. These are reflected in voxel-wise network centrality abnormalities in the precuneus (Di Martino et al. 2013) or task-related (sustained attention task) deviations in bilateral striato-thalamic regions, left dorsolateral PFC, superior parietal cortex, precuneus, and DMN suppression (Christakou et al. 2013). Furthermore, also grey matter reductions in the left medial temporal lobe and higher grey matter volumes in the left inferior parietal cortex were observed in ADHD and ASD adolescents compared with healthy controls (Brieber et al. 2007). Thus, shared neural network dysfunction might be present in both groups of patients. Reconsidering these findings in the context of the results gathered in the present meta-analysis, an interesting question for future studies is the involvement of the anterior rTPJ in attentional and social interaction difficulties in patients with ADHD and ASD. As there is a huge lack in neuroimaging studies focusing on reorienting of attention and false belief tasks in ADHD and ASD, it is currently infeasible to extend our ALE analyses to clinical groups. However, hopefully, our ideas on a potential linkage

between attention and social cognitive processes assigned to the rTPJ leads to more neuroimaging studies investigating potential difficulties in these patient groups.

Limitations

There are some limitations of the present meta-analysis that should be considered. Unfortunately, the ALE analysis does not include information on cluster and effect sizes (Decety and Lamm 2007). Additionally, the usage of peak coordinates might lead to mis- or over-interpretation of the results. Nonetheless, up-to-date ALE meta-analyses are as advanced as possible since statistical meta-analyses based on original data sets are not yet available. Only, when an agreement between researchers on data sharing has been achieved, meta-analyses with original data might be possible (Mar 2011).

Furthermore, the MACM and RSFC connectivity analyses imply some limitations regarding functional coupling with specific seed regions. For the MACM, the origin of the ensuing activation maps greatly differs from other connectivity approaches as this method does not rely on time series in the strict sense or any particular neuroimaging experiment (Eickhoff and Grefkes 2011). Rather, functional connectivity is reflected by congruency in co-activation probability across a large quantity of diverse experiments, not across time, which complements existing approaches of functional connectivity analyses. For the RSFC analysis, fMRI time series are obtained while participants are scanned in the absence of an externally structured task set. It has been recently shown that conclusions drawn on functional properties merely based on resting-state connectivity results should be interpreted carefully (Rehme et al. 2013). This is because resting-state and task-based connectivity reflect distinct components of functional integration depending on the functional state of the scanned subjects (reflection of inner mental states or reaction to external tasks, respectively; Rehme et al. 2013). Therefore, independent functional connectivity approaches such as dynamic causal modelling might add important information on the actual functional involvement of the anterior and posterior rTPJ networks in reorienting of attention and false belief tasks.

Conclusion

The current (ALE) meta-analysis resolves important aspects of the debate about the role of the rTPJ in attention and social interaction. The anterior rTPJ was identified as a single converging zone for reorienting of attention and false belief, which supports the overarching hypothesis (Cabeza et al. 2012). Findings are consistent with the

concept of an attentional shifting capacity in this region as previously proposed by Corbetta et al. (2008). ToM abilities may therefore be rooted on attentional shifting. This potential link is also reflected in developmental studies showing a strong association between early attentional capacities and later social cognition abilities (Rothbart et al. 2011; Mundy and Newell 2007).

On the other hand, posterior rTPJ was identified by a difference (ALE) analysis as significantly converging for false belief in contrast to reorienting of attention studies. This provides support for the fractionation view postulating that independent regions within the rTPJ support distinct cognitive functions (Cabeza et al. 2012). It seems that besides the importance of an attentional shifting capacity in false belief, linked to the anterior part of the rTPJ, the posterior part is more specifically involved in false belief compared with reorienting of attention (Bzdok et al. 2013a; Mars et al. 2012b).

MACM and RSFC were further performed to identify the differences in functional connectivity between the anterior and posterior rTPJ subregions. The anterior rTPJ in contrast to the posterior rTPJ showed connectivity to regions previously identified as part of a ventral attention network (Corbetta et al. 2008) associated with shifting of attention to behaviourally relevant stimuli. In contrast, the posterior rTPJ compared with the anterior rTPJ co-activated with a social network more globally involved in ToM-like abilities (Jackson et al. 2006; Ruby and Decety 2004). As MACM and RSFC are capable of adding essential information on the underlying connectivity of different regions aiding specific cognitive functions, it was possible to identify these two clearly functionally fractionated regions in the rTPJ: the anterior rTPJ involved in attentional shifting and the posterior rTPJ involved in social interaction capacities. Importantly, our ALE conjunction result identifying an overlap of reorienting of attention and false belief tasks in the anterior rTPJ is not contradicting the fractionated interpretation of our findings, as our connectivity analyses clearly suggest a contribution of this region to a role in attentional shifting.

Conflict of interest The authors declare that they have no conflict of interest.
